Perfect Foresight Is Almost Enough: Risk Corrections in Function Space for Nonlinear New Keynesian Models

Extended abstract

Jan Rosa* Mahdi Ebrahimi Kahou† Jesús Fernández-Villaverde‡

October 17, 2026

1 Introduction

This paper proposes a new method for solving nonlinear dynamic stochastic general equilibrium (DSGE) models that starts from the full solution of a simplified deterministic model and corrects it for stochastic risk in function space. We focus on New Keynesian models, but the method applies to any model whose deterministic version can be solved accurately, such as open-economy and international macro models or production-network models (Fernández-Villaverde et al., 2026a). The method has two steps. First, we solve the deterministic, i.e., perfect-foresight, version of the model, which can often be done efficiently and accurately with deep learning or kernel methods (Ebrahimi Kahou et al., 2024, 2026). Second, this solution serves as the initial point in function space for solving the full stochastic version of the model. The gap between the deterministic and the stochastic solution is closed by a Newton–Kantorovich iteration on the stochastic equilibrium conditions, the function-space analogue of Newton's method for a system of equations. Newton's method is fast when the initial guess is close to the solution, and the deterministic solution is close, since it misses only the effect of risk, which is of the order of the variance of the shocks.

Contribution Our contributions are threefold. First, we show that under regularity conditions on the equilibrium in a normed space, the deterministic solution is close to the full stochastic solution, with a distance in norm of the order of the variance of the largest shock in the model. Second, starting from the deterministic solution, we propose a Newton–Kantorovich algorithm that converges quickly to the stochastic solution. Third, to demonstrate the method, we solve nonlinear New Keynesian models with capital accumulation under both Rotemberg and Calvo pricing. The Calvo version with capital is notoriously nonlinear, and to the best of our knowledge no global solution of it exists: existing solutions rely on perturbation around the steady state, and global methods adopt Rotemberg pricing or drop capital.

Intuition of the paper The first step of our approach is to learn the solution of the deterministic problem. This solution already contains most of the information about the solution of the stochastic problem: the only missing element is the effect of stochastic shocks and uncertainty. The second step learns this missing element, which explains the fast convergence of our method. The deterministic solution also provides something subtler. Sampling the state space is challenging even in moderate dimension (Ebrahimi Kahou et al., 2021; Fernández-Villaverde et al., 2026b), and more so in highly nonlinear problems. Simulating the deterministic solution under the calibrated shocks delivers a region of the state space that is close, although not identical, to the region the stochastic economy visits. This also contributes to the robustness and efficiency of our method.

Why start from the deterministic solution? Three properties of the deterministic solution, documented by Ebrahimi Kahou et al. (2024, 2026) for neural networks and kernel machines, motivate this choice. First, the deterministic solution can be computed accurately and at low computational cost, as the deterministic problem is simpler, particularly when formulated in sequential form: finding the trajectory of the economy from given initial conditions. This sequential formulation also enables efficient, grid-free sampling by collecting the states visited along the trajectory. Second, through implicit or explicit regularization of solution paths, the resulting solution automatically satisfies the transversality and no-Ponzi conditions. This is particularly important for problems with hysteresis, which arise frequently in growth models (Skiba, 1978; Azariadis and Drazen, 1990) and open-economy models (Mendoza, 2010; Mendoza and Villalvazo, 2020). Third, because transversality conditions ensure the stability of equilibrium paths, a solution satisfying these conditions is stable, preventing errors from accumulating along the dynamics. Error accumulation is particularly problematic in highly nonlinear models, such as those studied in this paper.[1]

Related works Our work is related to several strands of the literature. First, the idea of exploiting the deterministic solution to solve stochastic models was introduced by Boppart et al. (2018), who compute first-order responses to aggregate shocks from a single perfect-foresight transition path. Their approximation is linear in the size of aggregate shocks and therefore certainty-equivalent: the effects of risk are absent by construction, whereas capturing them is precisely the object of our second step. Closest to us, Ajevskis (2017) constructs semi-global solutions as expansions in the volatility parameter around deterministic trajectories. Sequence-space methods (Auclert et al., 2021) likewise perturb equilibrium objects around a deterministic path. All three approaches share our anchor but deliver path-based objects: solutions attached to a particular initial condition and shock history, to be recomputed when either changes, and accurate to the order at which the expansion is truncated. In contrast, we correct the deterministic solution for risk over the whole state space and iterate to the exact stochastic solution: the output is the recursive equilibrium of the entire economy, computed once and valid for every shock history

This paper is also related to the broader perturbation literature. Standard perturbation methods (Schmitt-Grohé and Uribe, 2004; Fernández-Villaverde et al., 2016) expand policy functions around a single point, the deterministic steady state, and their accuracy degrades as the economy moves away from it, which is precisely the case in the highly nonlinear models we study. A theoretical branch of this literature studies when such expansions are valid: Judd and Guu (2001) develop asymptotic expansions in the volatility parameter, Jin and Judd (2002) establish the local validity of perturbation solutions via implicit-function arguments, Kim et al. (2008) analyze the accuracy of second-order approximations, and Lombardo and Uhlig (2018) prove convergence of the resulting

[1] This is a well-known problem in DSGE models, and solutions specific to individual numerical methods have been proposed, such as pruning in higher-order perturbation methods (Kim et al., 2008; Andreasen et al., 2018).

series expansions. Our first contribution belongs to this lineage but differs in the anchor and in the setting: we expand around the globally nonlinear deterministic solution rather than a steady state, and we establish the result for the system the method actually solves, the equilibrium conditions imposed on the sampled states, where the distance between the deterministic and stochastic solutions is of the order of the shock variance and the leading correction is identified and computable by a single linear solve. Accuracy away from the sample is then assessed by out-of-sample residual diagnostics rather than asserted.

Lastly, our paper is related to the literature that uses modern machine learning methods, in particular deep learning, to solve dynamic models in economics (Maliar et al., 2021; Azinovic et al., 2022; Ebrahimi Kahou et al., 2021; Han et al., 2026; Kase et al., 2022; Barnett et al., 2023; Fernández-Villaverde et al., 2023; Jungerman, 2023; Duarte et al., 2024; Payne et al., 2024). These methods train a neural network to minimize the residuals of the equilibrium conditions on a sample of states, starting from a random initialization and sampling the state space either on a grid or by simulating the current policy. We differ in two ways. First, our starting point is not random but the deterministic solution, which already contains most of the economics of the problem and leaves only the effect of risk to be learned. Second, the deterministic solution tells us where to sample, since simulating it under the calibrated shocks delivers a region close to the one the stochastic economy visits. This matters in highly nonlinear models: in our experience, a standard deep learning approach with adaptive sampling fails in the New Keynesian model with Calvo pricing and capital accumulation.

Application We apply the method to a New Keynesian model with capital under both Calvo and Rotemberg pricing. With a high elasticity of substitution, the Calvo pricing block is known to be strongly nonlinear (Ascari and Sbordone, 2014): the reset-price and price-dispersion recursions have singularities a few percentage points above the inflation target. We demonstrate that the Newton–Kantorovich iteration delivers stochastic policy functions whose equilibrium residuals are close to numerical zero along impulse responses and simulated paths, even in this case.

2 Model and parametrization

We use a standard New Keynesian economy with capital and Calvo pricing. To keep the exposition short, we do not add the standard shocks and mechanisms of medium-sized models (habits, investment adjustment costs, variable utilization, sticky wages, fiscal policy); the method does not depend on them.

Households. A representative household maximizes $\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \big[\log c_t - \psi \, l_t^{1+\eta}/(1+\eta) \big]$ subject to $c_t + k_t + b_{t+1}/p_t = w_t l_t + (1 + r_t - \delta)k_{t-1} + R_{t-1} b_t/p_t + T_t + F_t$. It saves in physical capital k_t (rental rate r_t, depreciation δ) and in nominal bonds b_{t+1} (gross rate R_t). With $\lambda_t = 1/c_t$ the first-order conditions are

$$\psi l_t^{\eta} = \lambda_t w_t, \qquad \lambda_t = \beta \, \mathbb{E}_t \left[\lambda_{t+1} \frac{R_t}{\Pi_{t+1}} \right], \qquad \lambda_t = \beta \, \mathbb{E}_t [\lambda_{t+1}(1 + r_{t+1} - \delta)] \,, \tag{1}$$

where $\Pi_t = p_t/p_{t-1}$ is gross inflation.

Firms. A competitive final-good producer aggregates intermediate varieties with elasticity of substitution ϵ. Intermediate producer i has the technology $y_{it} = e^{z_t} k_{it-1}^{\alpha} l_{it}^{1-\alpha}$ and rents inputs at w_t and r_t, so that the real marginal cost is common across firms, $\mathrm{mc}_t = (1-\alpha)^{-(1-\alpha)} \alpha^{-\alpha} \, w_t^{1-\alpha} r_t^{\alpha} e^{-z_t}$.

Prices are set à la Calvo: each period a fraction $1-\theta$ of firms resets its price. The optimal reset price relative to the price level, $\Pi_t^* = p_t^*/p_t$, is characterized by two auxiliary variables, the discounted sums of marginal costs and of revenues of the price setters,

$$g_t^1 = \lambda_t \,\mathrm{mc}_t\, y_t + \beta\theta\, \mathbb{E}_t\left[\Pi_{t+1}^{\epsilon} g_{t+1}^1\right], \qquad g_t^2 = \lambda_t\, \Pi_t^*\, y_t + \beta\theta\, \mathbb{E}_t\left[\Pi_{t+1}^{\epsilon-1} \frac{\Pi_t^*}{\Pi_{t+1}^*}\, g_{t+1}^2\right], \qquad \epsilon\, g_t^1 = (\epsilon-1)\, g_t^2, \tag{2}$$

and by the price index $1 = \theta\Pi_t^{\epsilon-1} + (1-\theta)(\Pi_t^*)^{1-\epsilon}$. Price dispersion $v_t = \int_0^1 (p_{it}/p_t)^{-\epsilon}\, di$ lowers aggregate supply, $y_t = e^{z_t} k_{t-1}^{\alpha} l_t^{1-\alpha}/v_t$, and evolves as $v_t = \theta\Pi_t^{\epsilon} v_{t-1} + (1-\theta)(\Pi_t^*)^{-\epsilon}$.

Monetary policy and shocks. The central bank follows a Taylor rule that responds to inflation and to output *growth*,

$$R_t = R\left(\frac{\Pi_t}{\Pi}\right)^{\gamma_\Pi}\left(\frac{y_t}{y_{t-1}}\right)^{\gamma_{\Delta y}} e^{\xi_t}, \qquad z_t = \rho z_{t-1} + \sigma_z \varepsilon_{z,t}, \qquad \xi_t = \rho_m \xi_{t-1} + \sigma_m \varepsilon_{m,t}, \tag{3}$$

with $\varepsilon_{z,t}, \varepsilon_{m,t} \sim \mathcal{N}(0,1)$.

Market clearing. $c_t + k_t = y_t + (1-\delta)k_{t-1}$.

Recursive formulation. The state is $s_t = (z_t,\, k_{t-1},\, \xi_t,\, v_{t-1},\, y_{t-1})$ and the policy is $f(s_t) = (k_t,\, l_t,\, \Pi_t,\, g_t^1)$. Given s_t and $f(s_t)$ every other date-t object follows in closed form: Π_t^* from the price index, v_t, y_t, c_t from market clearing, λ_t, w_t, r_t, mc_t, R_t, and g_t^2 from the reset-price condition. Market clearing therefore never appears as a residual. The four remaining conditions are the two Euler equations in (1) and the two Calvo recursions in (2); each is a ratio N/D that equals one at the solution, and we take the residual as $\log(D/N)$.

Explicitly, for a candidate policy f and a state $s = (z, k, \xi, v_{-1}, y_{-1})$, let $(k', l, \Pi, g^1) = f(s)$ and let $c, \lambda, y, v, \mathrm{mc}, r, R, \Pi^*, g^2$ be the date-t objects recovered from them as above. The successor state under the innovation $\varepsilon = (\varepsilon_z, \varepsilon_m)$ is

$$s'(\varepsilon) = \big(\rho z + \sigma_z \varepsilon_z,\ k',\ \rho_m \xi + \sigma_m \varepsilon_m,\ v,\ y\big), \tag{4}$$

and primed objects $(\lambda', \Pi', r', g^{1\prime}, g^{2\prime}, \Pi^{*\prime})$ are the same recovered quantities evaluated at $s'(\varepsilon)$ under the policy $f(s'(\varepsilon))$. The residual vector at s is

$$l(\sigma, f)(s) = \begin{pmatrix} \log\lambda - \log\left(\beta\, \mathbb{E}_\varepsilon\left[R\, \lambda'/\Pi'\right]\right) \\ \log\lambda - \log\left(\beta\, \mathbb{E}_\varepsilon\left[\lambda'(1 + r' - \delta)\right]\right) \\ \log g^1 - \log\left(\lambda\, \mathrm{mc}\, y + \beta\theta\, \mathbb{E}_\varepsilon\left[\Pi'^{\epsilon} g^{1\prime}\right]\right) \\ \log g^2 - \log\left(\lambda\, \Pi^*\, y + \beta\theta\, \Pi^*\, \mathbb{E}_\varepsilon\left[\Pi'^{\epsilon-1} g^{2\prime}/\Pi^{*\prime}\right]\right) \end{pmatrix}, \qquad g^2 = \tfrac{\epsilon}{\epsilon-1}\, g^1, \tag{5}$$

where $\mathbb{E}_\varepsilon$ is the expectation over $\varepsilon \sim \mathcal{N}(0, I_2)$, computed numerically as $\sum_q w_q\, (\cdot)(s'(\varepsilon_q))$ on the nodes $\{\varepsilon_q, w_q\}$ of the quadrature. The perfect-foresight residual $l(0, f)$ is the same expression with the expectation replaced by evaluation at the single zero-innovation successor $s'(0)$.

Calibration. Table 1 reports the calibration. The parameters are standard; the elasticity of substitution $\epsilon = 10$ and the Calvo parameter $\theta = 0.8$ place the singularities of the Calvo block two percentage points above the target.

Parameter	Description	Value
β	discount factor	0.99
α	capital share	1/3
δ	depreciation rate	0.025
η	inverse Frisch elasticity	1.0
ϵ	elasticity of substitution	10
θ	Calvo parameter (share of firms that cannot reprice)	0.8
Π	inflation target (gross, quarterly)	1.005
γ_Π	Taylor rule: response to inflation	2.0
$\gamma_{\Delta y}$	Taylor rule: response to output growth	0.5
ρ	TFP persistence	0.95
σ_z	TFP innovation std. dev.	0.007
ρ_m	monetary persistence	0.9
σ_m	monetary innovation std. dev.	0.001

Table 1: Calibration. The labor disutility weight ψ is not a free parameter: it is set to w/c at the steady state so that $l = 1$. The implied steady state has $k = 24.9$, $\lambda = 0.44$, $g^1 = 6.8$, and $v = 1.0033$.

2.1 The Calvo singularities and the precision they demand

The Calvo block is not a smooth deformation of the flexible-price economy: three of its objects have singularities a few percentage points above the target.

- *Reset price.* The price index gives $\Pi_t^* = \big((1-\theta\Pi_t^{\epsilon-1})/(1-\theta)\big)^{1/(1-\epsilon)}$, which diverges at $\bar{\Pi} = \theta^{-1/(\epsilon-1)}$, the inflation rate at which the non-resetting firms alone exhaust the price index. Its elasticity with respect to inflation, $\theta\Pi^{\epsilon-1}/(1-\theta\Pi^{\epsilon-1})$, is already 5.1 at the target and grows without bound.
- *Marginal-cost sum.* At constant inflation $g^1 = \lambda\,\mathrm{mc}\,y/(1-\beta\theta\Pi^\epsilon)$, with a pole at $\tilde{\Pi} = (\beta\theta)^{-1/\epsilon}$. The elasticity of g^1 with respect to inflation at the target is $\epsilon\beta\theta\Pi^\epsilon/(1-\beta\theta\Pi^\epsilon) \approx 50$: a 1% error in the inflation policy moves the g^1 condition by 50%, so the forward-looking pricing conditions amplify, rather than damp, errors in inflation.
- *Price dispersion.* The recursion $v_t = \theta\Pi_t^\epsilon v_{t-1} + (1-\theta)(\Pi_t^*)^{-\epsilon}$ has autoregressive coefficient $\theta\Pi^\epsilon$, equal to 0.84 at the target and to one at $\Pi_v = \theta^{-1/\epsilon}$; beyond it dispersion, and with it the output loss, grows without bound.

At $\theta = 0.8$ and $\epsilon = 10$ the three poles are at $\bar{\Pi} = 1.0251$, $\tilde{\Pi} = 1.0236$ and $\Pi_v = 1.0226$, i.e. 1.8 to 2.0 percentage points of quarterly inflation above the target.

Two consequences follow. First, the stochastic economy visits neighborhoods of the poles: sequences of adverse shocks push inflation toward the region where all three elasticities explode, so the solution must be most accurate precisely where the model is most nonlinear. Second, the poles bound the domain of any expansion around the steady state: a Taylor series in inflation cannot be valid beyond the nearest singularity, less than two percentage points away, whatever its order. A global and highly accurate solution is therefore not a refinement but a requirement. Moreover, since the poles are properties of Calvo's aggregation, none of this structure exists under Rotemberg pricing, whose adjustment cost is a smooth quadratic: the two blocks, identical to first order, are globally different economies.

How accurate is dictated by how residuals translate into allocations, and here the model is demanding in two opposite directions at once. The *nominal* direction is stiff. With the g^1 elasticity of fifty, an inflation-policy error of one percent moves the pricing conditions by fifty percent, so the residuals react violently to small errors in inflation; this makes the training landscape severely

anisotropic, but it also means that small residuals pin down inflation tightly. The *real* direction is flat. At a fixed point of a candidate policy, $\lambda' = \lambda$ and the capital Euler residual, the second row of (5), reduces to $l_2 = -\log\big(\beta(1 + r - \delta)\big)$; because the rental rate falls with capital, $r \propto k^{\alpha-1}$, the steady state the policy actually converges to is off by

$$\frac{\Delta k}{k} \;\approx\; \frac{l_2}{\beta\, r_{ss}(1-\alpha)} \;\approx\; 43\, l_2$$

at our calibration ($r_{ss} = 1/\beta - 1 + \delta = 0.035$). The long-run return on capital is extremely flat, so here the translation runs the other way: a capital Euler residual of 5×10^{-3}, small by the usual standards of the literature, silently misplaces the long-run capital stock by more than 20%. The flat direction therefore sets the residual target, and the stiff direction makes that target hard to reach. The effective conditioning between the two is of order 10^3, which is why first-order training methods stall on this model and a Newton stage is needed to push below it.

3 Solution method

3.1 The perfect-foresight policy as the starting point

The policy is a neural network $f(\cdot\,;\vartheta)$ with parameters ϑ, and the equilibrium conditions are imposed on a finite sample of states $\{s_i\}_{i=1}^N$ obtained, as described below, by simulating the model. Stacking (5) over the sample gives a finite-dimensional residual map

$$L(\sigma, \vartheta) = \big(l(\sigma, f(\cdot\,;\vartheta))(s_i)\big)_{i=1}^N \in \mathbb{R}^{4N}, \tag{6}$$

and what we compute is a parameter vector ϑ_σ with $L(\sigma, \vartheta_\sigma) = 0$. Let ϑ_0 be a perfect-foresight solution, $L(0, \vartheta_0) = 0$. Two facts about L drive the method. The shock scale σ enters only through the successor states $s'(\sigma\varepsilon_q)$ inside the expectations, and the quadrature nodes are symmetric, $\sum_q w_q \varepsilon_q = 0$, so $\partial_\sigma L(0, \vartheta) = 0$ for every ϑ: the first-order effect of risk cancels at every sampled state, not only at the steady state.

Proposition 1 (informal)**.** *Assume L is twice continuously differentiable in σ and that the Jacobian $J(\vartheta) = \partial_\vartheta L(\sigma, \vartheta)$ has full row rank and is Lipschitz in a neighborhood of ϑ_0. Then: (i) $\|L(\sigma, \vartheta_0)\| \le \frac{1}{2} \sup_{s\in[0,\sigma]} \|\partial_\sigma^2 L(s, \vartheta_0)\|\, \sigma^2$, i.e. the perfect-foresight parameters solve the stochastic equations on the sample up to $O(\sigma^2)$; (ii) there is a stochastic solution with $\|\vartheta_\sigma - \vartheta_0\| \le C\sigma^2$; (iii) the Newton–Kantorovich iteration $\vartheta_{n+1} = \vartheta_n - J_n^\top (J_n J_n^\top)^{-1} L(\sigma, \vartheta_n)$, $J_n = J(\vartheta_n)$, converges quadratically to ϑ_σ, and for σ small enough ϑ_0 lies in its basin of attraction (Kantorovich and Akilov, 1982; Deuflhard, 2004).*

Part (i) says that the deterministic solution already satisfies the stochastic equations up to the variance of the shocks, (ii) that it is also close in parameters, and (iii) that Newton started from it works: the first step removes the $O(\sigma^2)$ error and leaves $O(\sigma^4)$ (taken with the Jacobian at $\sigma = 0$, this step is the second-order functional correction), and the next steps reach the numerical floor. The statement is about the sampled system only: nothing is claimed between the sample points, and the quality of the policy there is checked afterwards on fresh simulated paths.

3.2 Algorithm

Three stages: solve perfect-foresight paths and use them to build the state sample and the starting policy; fit the neural network to those paths; run Newton–Kantorovich on the stochastic equations.

1. Perfect-foresight paths and the state sample. For a given initial state we solve the perfect-foresight path $\{k_t, l_t, \Pi_t, g_t^1\}_{t=0}^{T-1}$: the residuals (5) at $\sigma = 0$, written at every date, form a square nonlinear system in the path, closed at date T by the linear saddle-path policy, and Newton solves it to machine precision in a fraction of a second. By time consistency the date-0 values of the path are the perfect-foresight policy at the initial state, so every solved path is one exact (state, policy) pair. To cover the states the model actually visits we simulate the perfect-foresight policy under the calibrated shocks: we solve the path at the current state, move to its date +1 state, add one shock innovation, solve again. The result is a sample from the ergodic set of the model, 1,200 states from eight chains, with no grid on any state.

2. Fitting the network. The policy is a neural network (2,628 parameters in total). Neural networks are a flexible family of functions that is cheap to evaluate and to differentiate at scattered states, which is what the sample is. The network is fitted by least squares to the exact pairs of stage 1. Optionally, the deterministic Newton–Kantorovich iteration (stage 3 with $\sigma = 0$) polishes the fit.

3. Newton–Kantorovich. Expectations use the degree-5 monomial rule of Judd et al. (2011), nine nodes for two shocks. One round of the method consists of the following stages:

1. *Simulate.* Find the risky steady state of the current policy (the fixed point of its zero-shock dynamics) and simulate eight shocked paths of 34 periods from it under the current policy; keep dates 10 to 33, i.e. 192 states $\{s_i\}$. The sample is then frozen for the round.
2. *Linearize.* At the current parameters ϑ_n, compute the residuals $L(\sigma, \vartheta_n)$ on the sample and their Jacobian J_n with respect to the network parameters by automatic differentiation. Each residual depends on the policy at s_i and at its nine successors s'_{iq}, so J_n has two parts: the direct effect of $f(s_i)$ and the effect through $f(s'_{iq})$ and through the location of the successor itself, which moves with today's k' and v.
3. *Step.* Solve the linear least-squares problem $\min_d \|L(\sigma, \vartheta_n) + J_n d\|^2$ for its minimum-norm solution (768 rows against 2,628 parameters, so the minimum-norm choice is the regularizer) and set $\vartheta_{n+1} = \vartheta_n + t\,d$, with $t \leq 1$ chosen by a line search on the largest residual.
4. *Repeat.* Ten iterations of steps 2 and 3, then back to step 1: the ergodic set moves with the policy, so the sample is resimulated.

Before the first stochastic round the level and slope of the network at the steady state, fixed during the deterministic stages, are freed, because the risky steady state differs from the deterministic one. Accuracy is always judged on fresh simulated paths that the solver never trained on.

4 Results

We report the Calvo results.

Deterministic phase. From the supervised fit, the deterministic Newton iteration drives the sup-residual on the cloud from 8.3×10^{-5} to 3.0×10^{-5} and then 4.3×10^{-6}, where the line search stops accepting steps. On the 600 held-out states the sup-residual is 7.9×10^{-4}, set by the extreme states of the test chains that lie outside the training range (one chain reaches $k = 1.12\,k_{ss}$), and the mean policy error against the exact perfect-foresight solution is of order 10^{-5} in every output. Zero-shock transitions from $k_{ss}(1 \pm 0.05)$ return to the steady state to 10^{-8} with a half-life of 13 quarters.

Stochastic policy: impulse responses. Figure 1 shows impulse responses of the stochastic policy to one-off two-standard-deviation innovations, computed at the risky steady state and differenced against the zero-shock baseline from the same point. A negative TFP innovation of 1.4% raises inflation by 0.21 percentage points on impact and hours by 1.5%, since the growth rule lets the central bank accommodate the fall in output; output falls by 0.5% on impact and by 1.35% at the trough eight quarters out, capital by 1.1% after twenty quarters, and price dispersion rises for about fifteen quarters. A positive monetary innovation lowers inflation by 0.18 percentage points, hours by 0.24% and investment, so that capital falls by 0.11%; the equilibrium nominal rate falls because the rule's response to lower inflation and output growth more than offsets the innovation. The last column grades the equilibrium residual along the response with the nine-node rule: it stays between 10^{-7} and 4×10^{-6} at every date of both responses.

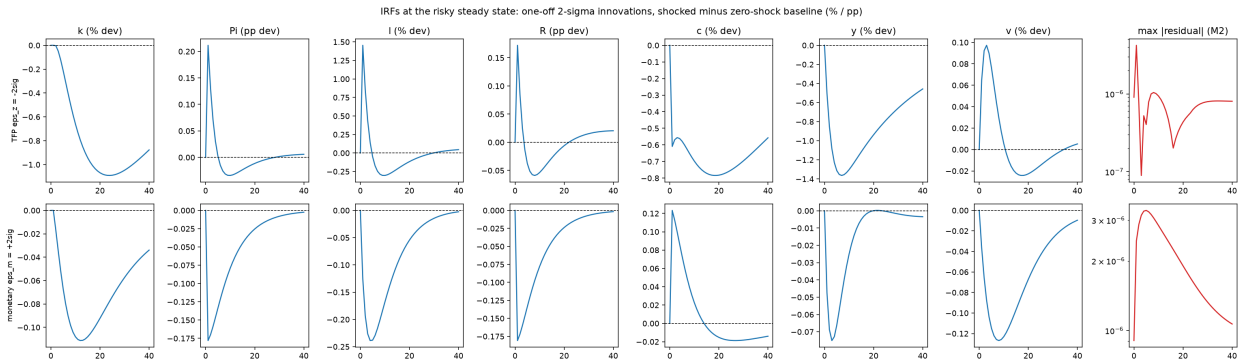

Figure 1: Impulse responses of the stochastic policy at the risky steady state to one-off 2σ innovations (top: TFP, $\varepsilon_z = -2\sigma_z$; bottom: monetary, $\varepsilon_m = +2\sigma_m$), shocked minus zero-shock baseline, in percent or percentage points. The last column is the maximum absolute equilibrium residual over the four conditions, graded with the degree-5 monomial rule.

Stochastic policy: simulation. Figure 2 shows 36 simulated paths of 100 quarters from the risky steady state under the calibrated shocks, with the median per panel. Table 2 summarizes the residuals. No path leaves the region where the model is well defined; inflation ranges from 0.994 to 1.013 against the singularity at 1.0236, price dispersion reaches 1.022, and capital moves between 0.92 and 1.07 times its steady-state value. The equilibrium residual has mean 3.5×10^{-5} and median 7×10^{-6} over the 3,600 simulated states, a 99th percentile of 4×10^{-4}, and a maximum of 1.3×10^{-3}, reached at the most extreme dispersion states, which lie at the edge of the resimulated clouds.
